Reputation Inflation*

Apostolos Filippas† John J. Horton‡ Joseph M. Golden§
March 5, 2020

Abstract
A solution to marketplace information asymmetries is to have trading partners publicly rate each other post-transaction. Many have shown that these ratings are effective; we show that their effectiveness can deteriorate over time. The problem is that ratings are prone to inflation, with raters feeling pressure to leave “above average” ratings, which in turn pushes the average higher. This pressure stems from raters’ desire to not harm the rated seller. As the potential to harm is what makes ratings effective, reputation systems, as typically designed, become less informative in the long-run.

1 Introduction

Scores of various kinds—credit scores, school grades, restaurant and film “star” reviews, restaurant hygiene scores, Better Business Bureau ratings—have long been important sources of information for market participants. A large literature documents the economic importance of such scores (Resnick et al., 2000; Jin and Leslie, 2003; Resnick et al., 2006; Mayzlin et al., 2014; Ghose et al., 2014; Luca, 2016; Luca and Zervas, 2016). As more of economic and social life has become computer-mediated, opportunities to generate and apply new kinds of scores—particularly in marketplace contexts—have proliferated, as has the number of individuals and businesses subject to these “reputation systems” (Levin, 2011; Hall and Krueger, 2018; Katz and Krueger, 2019). Designing effective reputation systems has become a first-order question in the digital economy.

In online marketplaces, “reputations” are typically calculated from numerical feedback scores left by past trading partners. As many have noted, the distribution of feedback scores in various online marketplaces seems implausibly rosy.¹ For example, the median seller on eBay has a score of 100% positive feedback ratings, and the tenth percentile is 98.21% positive feedback ratings (Nosko and Tadelis, 2015). On Uber and Lyft, it is widely known that anything less than 5 stars is considered “bad” feedback: Athey et al. (2019) find that nearly 90% of UberX Chicago trips in early 2017 had a perfect 5-star rating.

Of course, there is no ground truth that tells us what the distribution of scores in some market should look like at a moment in time. However, if we look at how the distribution of scores changes over time, we can potentially learn more about what the reputation system is measuring. Two distinct—but not mutually exclusive—reasons can cause rising feedback scores: (1) raters are becoming more satisfied, or (2) raters are lowering their rating standards. The first possibility—more satisfied employers giving higher scores—is due to improvements in market “fundamentals,” such as better marketplace features, better cohorts of employers/workers joining the platform, lower-priced products, and less picky employers.² The second possibility—giving higher scores despite not being more satisfied—can be thought of as a kind of inflation. This “reputation inflation” erodes the comparability of feedback scores over time, and can reduce the informativeness of a reputation system.³

¹A PEW research center survey finds that while more than 80% of U.S. adults read online reviews before purchasing an item, almost 50% find the truthfulness of these reviews hard to assess. For more details, see http://www.pewinternet.org/2016/12/19/online-reviews.
²We use the terms “employer” and “worker” for consistency with the literature, and not as a comment on the legal relationship of the transacting parties.
³This kind of inflation is similar to the conjecture about the increase in college grades—namely, that students’ work is not getting better, but rather that the same quality of work now earns a higher grade (Babcock, 2010; Butcher et al., 2014).
In this paper, we examine the reputation system of a large online labor market, focusing on the evolution of average feedback scores over time, and the causes for the dynamics we observe. Mirroring findings from other marketplaces, we find that the distribution of recent employer feedback for workers is highly top-censored, with an overwhelming majority receiving perfect feedback. However, the distribution has not always been this skewed—the fraction of workers receiving a perfect 5-star rating grew from 33% to 85% in just 6 years. Feedback scores in four other online marketplaces for which we obtained longitudinal data exhibit a similar increase over time.

To examine whether the increase is caused by raters becoming more satisfied or by raters lowering their rating standards, we use longitudinal data that include both the feedback scores and an alternative measure of rater satisfaction. The idea is that if rater satisfaction is also captured by an alternative measure that does not inflate—or inflates at a lower rate—then we can exploit this difference to produce an estimate of inflation in the measure of interest.

As a first alternative measure of rater satisfaction, we use information obtained by the introduction of a parallel and experimental reputation system that asked employers to rate workers “privately.” This private feedback was not conveyed to the rated workers, nor made public to future would-be employers. At the same time, raters were still asked to give the status quo “public” feedback, both written and numerical. The conjecture motivating the platform’s private feedback feature was that employers would be more candid in private, willing to give “bad” feedback if not exposed to retaliation from angry workers, and/or because a “bad” report would not harm the worker. We find that average private feedback scores were decreasing over the period they were collected, but at the same time average public feedback scores for the same transactions were increasing. This difference helps to disentangle the two reasons that can cause rising feedback scores: employers were not becoming more satisfied, but instead they were lowering their rating standards for public feedback.

As a second alternative measure of rater satisfaction, we use the sentiment employers express in the written feedback that accompanies numerical scores. To capture this sentiment, we fit a model that predicts numerical feedback from the text of written feedback. Critically, the model is fit using written feedback from a narrow window of time early in our data, allowing us to learn the relationship that prevailed between written sentiment and numerical score when the training feedback text was created. Using the predictions of the model, we can then decompose the growth in average feedback scores into a component due to improvements in market fundamentals that increased rater satisfaction and is reflected in written feedback, and the residual component that is due to inflation. We find that although
predicted feedback scores based on written feedback have increased over time, presumably due to improvements in fundamentals, they have not increased nearly as much as the numerical feedback scores. Our estimates suggest that more than 50% of the increase in scores over a 6 year period was due to inflation, and are robust across different specifications and training sets. Furthermore, insofar written feedback is also subject to inflation, our approach understates the extent of reputation inflation.

As a less model-dependent approach, we also compare the numerical feedback scores associated with the same common sentences appearing in written feedback in two different time periods. We show that the same sentences systematically have higher associated numerical feedback scores in the latter period. For example, employers calling the work they received “terrible” would assign on average a public feedback score of 1.4 stars in 2008, but they would instead assign 2.4 stars in 2015.4

We next turn to understanding the cause of reputation inflation. We argue that the key to understanding reputation inflation is appreciating the role of costs, and how these costs affect raters. A starting point is the divergence between public and private feedback scores: 28.4% of those employers that privately report that they would definitely not hire the same worker in the future, publicly assign them 4 or more stars out of 5. The reverse essentially never happens—raters giving “good” private feedback and “bad” public feedback. The likely reason is that “bad” public feedback is costly in a way that “bad” private feedback is not. For example, employers may still fear that workers who receive “bad” feedback will retaliate by complaining, bad-mouthing the rater, or withholding future cooperation It is important to note that rated workers on the focal platform cannot retaliate by giving the employer bad feedback, because employer and worker feedback are revealed simultaneously (Bolton et al., 2013). Furthermore, employers may simply not want to harm the ratee’s future prospects, as public feedback is consequential. Together, these “reflected” costs make giving “bad” feedback costlier to the rater than giving “good” feedback.

The cost of giving “bad” feedback could explain why feedback scores are higher than they would be if more employers reported truthfully. However, it cannot by itself explain the dynamics of ever-higher scores we observe: inflation requires the cost of leaving a given “bad” score to increase over time. We hypothesize this is precisely what happens: the same nominal feedback score (e.g., 2 “stars”) becomes costlier to the rated worker over time,

4In addition to employing alternative measures of rater satisfaction to estimate the extent of reputation inflation, we also directly test alternative hypotheses that could explain the over time increase in feedback scores. In Appendix A, we provide tests that directly rule out several plausible explanations, including changes in employer, worker, and task composition, as well as trading partner selection. Furthermore, Appendix B verifies that the private feedback measure was not misinterpreted by the employers, and provides tests ruling out selection concerns in giving private feedback. Appendix C rules out selection and composition concerns in giving written feedback, and provides robustness tests for the predictive modeling approach.
and hence costlier for the rater to give. In other words, the cause of inflation is that what constitutes “bad” feedback—feedback that causes worse market outcomes for raters receiving that score—is endogenous, depending on the current distribution of feedback scores, which in turn determines what inferences future buyers make from a score.

We formally illustrate how reputations can inflate through a simple model of a marketplace with a reputation system. We show that, in this model, there exists a unique and stable equilibrium in which reputations are universally inflated, because employers are more likely to report “good” feedback, regardless of actual worker performance, even when raters derive some benefit from telling the truth. The degree of reputation inflation depends on how much cost the rated party that receives “bad” feedback can impose on the rater who gives it; this could explain why in less personal settings—such as consumers rating products on Amazon or restaurants on Yelp—ratings are more spread out. In contrast, inflation is likely more acute in highly “personal” settings, such as on peer-to-peer platforms (Einav et al., 2016; Filippas et al., forthcoming).

To test our model’s claim that reflected costs cause inflation, we report quasi-experimental evidence from a platform intervention that allows us to test the predictions of our model. After collecting private feedback for 10 months, the platform began publicly releasing batched aggregates of this private feedback score to future would-be employers, thereby making private feedback consequential to workers. This batching kept private feedback quasi-anonymous, because the worker would not know which particular employer gave which feedback—unless every rater in the batch gave the lowest or highest possible rating. Furthermore, as the platform chose to only display average private feedback scores for each worker, workers could not see past private feedback scores assigned by would-be employers.

The private feedback quasi-experiment created a positive shock to the cost of “bad” private feedback for workers, allowing us to test our hypotheses that (1) the rater’s choice of what score to give is “strategic”—in the sense that employers consider the likely costs and benefits to what they report—and hence are more candid in private because there are no reflected costs, and (2) employers incur a cost analogous to the rated employers’ cost of receiving “bad” feedback when costs are introduced by the switch to public revelation, and inflation occurs. Importantly, this policy change would have different effects depending on the structure of these costs. If employers only want to avoid worker retaliation, then we should observe no effect, because giving “bad” feedback to workers cannot “get back” to the employers. However, if employers do not want to harm workers’ future prospects, then private feedback scores will start inflating. Of course, introducing a new, potentially more informative feedback measure may have caused improvements in fundamentals, and hence we still need to disentangle the effect of improvements in fundamentals from inflation on the
observed changes, as we did with the whole history of feedback scores.

We find that when the platform suddenly made private feedback scores public, private feedback scores began increasing immediately, but there was limited change in the sentiment of written feedback—the no-longer-private feedback became inflated, mirroring what we observed with public feedback. This result implicates the role of the “reflected” cost of “bad” feedback: when “bad” feedback became costlier to receive for workers, it also became costlier to give for employers, and there was less “bad” feedback. As “bad” feedback became scarce, what was mildly negative before became very negative, starting the inflation process described in our model.

Our paper makes several contributions. Our key contribution is documenting the extent of reputation inflation in a large online marketplace, and identifying its root cause. Our long-run, whole-system perspective is possible because we use data spanning over a decade of the operations of the marketplace. We suspect the reputation inflation problem is likely widespread, given that many online marketplaces share the same features as the one we study in depth, and nearly all have those features that we show lead to inflation. Our collection of longitudinal data from other platforms supports this view—in every marketplace for which we could obtain data, we observe average feedback scores increasing, even though each of these marketplaces do not allow “tit-for-tat” rating behavior (Bolton et al., 2013).

While our paper is not the first to explain how reputations can be biased, previous worked has focused on cross-sectional data (Dellarocas and Wood, 2008; Tadelis and Zettelmeyer, 2015; Tadelis, 2016; Hu et al., 2017). We believe ours is the first paper to take a longitudinal approach and show how individually rational choices about what feedback to leave push the market towards a less informative equilibrium, as to establish that the ever-higher reputation scores are to a large extent due to reputation inflation. Our analysis of the public revelation quasi-experiment highlights the key role of costs to raters, and that these costs are hard to diminish: making feedback anonymous failed to counteract inflation. Insofar that employers know “bad” feedback is consequential to workers, employers find it costly to assign “bad” feedback—even if the rated individual cannot retaliate. This suggests an inherent tension between ratings being consequential and ratings being informative; whether reputation systems less prone to inflation can be designed remains an open research question.

The rest of the paper is organized as follows. Section 2 surveys related literature, introduces the empirical setting, and documents increasing feedback scores over time across five online marketplaces. Section 3 employs two alternative measures of rater satisfaction to show that the feedback score increase in the focal platform is largely due to reputation inflation. To examine the causes of reputation inflation, Section 4 presents a simple theoretical framework, and Section 5 examines the quasi-experimental revelation of private feedback
information. Section 6 concludes.

2 Empirical context

2.1 Related work

The setting for our study is a large online labor market. In online labor markets, employers hire workers to perform remote tasks, such as computer programming, graphic design, and data entry. Online labor markets differ in their scope and focus, but services provided by the platform are similar to those provided by other peer-to-peer markets, and include maintaining job listings, arbitrating disputes, certifying worker skills and, importantly, building and maintaining reputation systems (Horton, 2010; Filippas et al., forthcoming). Online markets offer a convenient setting for research due to the excellent measurement afforded in the online setting, and the ease of conducting field experiments (Horton et al., 2011).

One particular focus of the online market design literature has been reputation systems. There is overwhelming evidence that reputation systems are economically significant, and confer substantial benefits for online markets by reducing moral hazard and adverse selection for market participants (Resnick et al., 2000; Dellarocas, 2003; Jin and Leslie, 2003; Resnick et al., 2006; Cabral and Hortaçu, 2010; Mayzlin et al., 2014; Ghose et al., 2014; Stanton and Thomas, 2015; Luca, 2016; Luca and Zervas, 2016; Benson et al., 2019). Our paper contributes to a burgeoning literature stream examining factors that may decrease the informativeness of reputation systems, and hence reduce their positive market effects.

One threat to reputation systems is that feedback scores are prone to manipulation by malevolent users. Mayzlin et al. (2014) examine firms’ incentive to create fake reviews by exploiting the difference in reviews for a given hotel between Expedia, where only customers can post reviews, and TripAdvisor.com, where everyone can post reviews. In the same empirical context, Luca and Zervas (2016) analyze restaurant reviews that are identified by Yelps filtering algorithm as suspicious or fake, and find that such reviews have increased over time, and that restaurants generate fake reviews strategically. The features of the reputation system in our focal marketplace make it less prone to feedback manipulation, including that employers may only leave reviews post-transaction, and that feedback scores are the dollar-weighted average of past transactions.

Even in the absence of review manipulation, reputation system features typically make negative feedback hard to elicit. One such feature is allowing firms to respond to consumer reviews. Proserpio and Zervas (2017) investigate the relationship between a firms use of management responses and its online reputation in the hotel industry; they find that ho-
hels start responding after a negative shock to their ratings, and that when hotels start responding, they receive fewer but longer negative reviews. Proserpio and Zervas argue that unsatisfied consumers become less likely to leave short indefensible reviews when hotels are likely to scrutinize them, and find that once hotels start responding, they attract reviewers who are inherently more positive in their evaluation. By contrast, Chevalier et al. (2018) argue that negative reviews are more likely to be stimulated by managerial responses, because potential reviewers perceive negative reviews to be more impactful—a claim which the authors also corroborate with experimental evidence. Ma et al. (2015) examine the effect of a firm’s service intervention in response to a compliment or a complaint on Twitter on the consumer’s subsequent Twitter comments. More specifically, Ma et al. show that redress seeking is a major driver of complaints, and hence an intervention may actually encourage future complaints.

In order to prevent conditioning, rebate-seeking, and tit-for-tat behavior, feedback is revealed simultaneously in bilateral reputation systems of platforms including Airbnb, Uber, and our focal platform (Bolton et al., 2013). Despite this feature, the hardness of eliciting negative feedback persists: Fradkin et al. (2019) find that introducing simultaneously revealed Airbnb reviews reduced the percentage of 5-star ratings by only 1.2%. Similarly to our findings, Fradkin et al. (2019) find a divergence between private and public feedback. Fradkin et al. attribute this difference to the reciprocity of the transacting parties, which is further corroborated by Proserpio et al. (2018). Adding to these findings, find present evidence that the divergence between public and private scores persists even in the case of remote transactions, but diminishes when the latter become more consequential.

Our paper also contributes to empirical studies of the long-run behavior of reputation systems, which has received little attention, perhaps due to the difficulty of obtaining longitudinal data. Previous has work focused on feedback scores in the context of online retail markets. Li and Hitt (2008) examine data from Amazon, and find evidence that consumers with higher valuations for a product are more likely to be early adopters, which can cause a decreasing trend in feedback scores. Godes and Silva (2012) find that the average Amazon review becomes more negative over time, which can be partially explained by a decrease in the diagnosticity of previous reviews. We highlight the need for a longitudinal view, documenting increases in feedback scores across five online peer-to-peer markets, and how the resulting top-censoring severely diminishes the informativeness of these scores. We also contribute to this literature by examining peer-to-peer markets, which are distinctly different than retail markets.

Disentangling changes in quality from inflation is a common problem in estimating monetary inflation, and inflation in non-digital contexts (Sidrauski, 1967; Friedman, 1977; Diewert,
A related problem is the challenges faced by firms measuring customer satisfaction. In particular, measuring satisfaction can be made hard because of the common method bias, attenuation bias due to measurement errors, and omitted variable bias (Kamakura, 2010; Podsakoff et al., 2012; Büschken et al., 2013; Huang and Sudhir, 2019). Our approach attempts to bypass the problem of estimating the relationship of consumer satisfaction and feedback score measures in cross-sectional data, by instead measuring changes over time.

2.2 Status quo reputation system

On the focal platform, when one party ends a contract both parties are prompted to give feedback.\(^5\) Employers are asked to give both written feedback, e.g., “Paul did excellent work—I’d work with him again” or “Ada is a great person to work for—her instructions were always very clear,” and numerical feedback. The numerical feedback is given on several weighted dimensions: “Skills” (20%), “Quality of Work” (20%), “Availability” (15%), “Adherence to Schedule” (15%), “Communication” (15%) and “Cooperation” (15%). On each dimension, the rater gives a score on a 1-5 scale.

The scores are aggregated according to the dimension weights. A worker’s reputation at a moment in time is the average of her scores on completed projects, weighted by the dollar value of each project. On the worker profile, a lifetime score is shown as well as a “last 6 months” score, which is more prominently displayed. Showing recent feedback is presumably the platform’s response to the opportunism that becomes possible once a employer or worker has obtained a high, hard-to-lower reputation (Aperjis and Johari, 2010; Liu, 2011). Despite the aggregation of individual scores into a reputation, the entire feedback “history” is available to interested parties for inspection. Workers can view the feedback given to previous workers rated by that employer, and the feedback received by an employer from that same worker.

The reputation system could be characterized as state-of-the-art for a bilateral system, in the sense that direct tit-for-tat conditioning is not possible (Dellarocas, 2005; Bolton et al., 2013; Fradkin et al., 2019). Both the employer and the worker have an initial 14 day “feedback period” in which to leave feedback. The platform does not reveal public feedback immediately. Rather, the platform uses a “double-blind” process. If both parties leave feedback during the feedback period, then the platform reveals both sets of feedback simultaneously. If only one party leaves feedback, then the platform reveals it at the end of the feedback period. Thus, neither party learns its own rating before leaving a rating for

\(^5\)We use the present tense here to describe the reputation system before the introduction of private feedback.
the other party. Leaving feedback is not strongly encouraged, but not compulsory. These encouragements seem effective, in that over the history of the platform, 81.8% of employers eligible to leave feedback have chosen to do so.

2.3 Feedback now and in the past

The distribution of employer-on-worker feedback scores in the market is highly right-skewed, but has not always been that way—scores have increased sharply over time. Most of the increase is explained by an increasing share of contracts receiving perfect feedback. These features of the data can be seen in the three panels of Figure 1.

Figure 1a depicts the histogram of public feedback scores from January 1, 2014 to May 11, 2016, for contracts worth more than $10.\(^6\) Public feedback scores are between 1 and 5 stars, inclusive, and with increments of 0.25 stars. Each bar is labeled with the percentage of total observations falling in that bin, and the red dashed line shows the cumulative number of assignments with feedback less than or equal to the right limit of the bin it is above. We observe that more than 80% of the evaluations fall in the 4.75 to 5.00 star bin (1,339,071 observations). The average feedback pooled for the whole sample shown in Figure 1a is 4.77.

Scores have not always been highly right-skewed. Figure 1b shows the average monthly feedback over time, for contracts ending within each month. There is a clear increase in the feedback scores awarded on the platform: the feedback score average has increased from 3.74 in the beginning of 2007, to 4.85 in May 2016. The strongest period of increase was 2007, when average feedback scores increased by about 0.53 stars.

The increase in average feedback could be the outcome of raters giving less “bad” feedback, more “good” feedback, or some combination thereof. Figure 1c shows the fraction of contracts having a rating within different ranges, over time. In the early days of the platform rating assignments were reasonably dispersed, with completed contracts regularly receiving ratings in the (0,3] range. Near the end of our data, completed contracts essentially never receive a rating in the (0,3] range. Instead, there has been a dramatic increase in the fraction of contracts getting exactly 5 stars: 33% of contracts received a 5-star rating at the start of sample, compared to 85% at the end of the sample.

\(^6\)We use this $10 restriction throughout the paper to remove mistaken, trial, and erroneous transactions.
Figure 1: Employer-on-worker feedback characteristics in an online marketplace

(a) Distribution of feedback scores for the period January 1, 2014 to May 11, 2016.

(b) Monthly average public feedback scores assigned on completed projects.

(c) Percentage of completed projects receiving different star ratings over time.

Notes: The top panel shows the histogram of public numerical ratings assigned by employers to workers, discretized by 0.25 star interval bins. The scale for feedback is 1 to 5 stars. The value of each bin is shown above it, and the red line depicts the empirical cumulative density function. The sample we use consists of all contracts from January 1, 2014 to May 11, 2016, for which the employer provided feedback. See Section 2.3 for the description of the sample. The middle panel plots the average public feedback scores assigned by employers to workers on completed contracts by month. The average scores are computed for every month, and a 95% interval is depicted for every point estimate. The shaded area denotes the data that was used in Figure 1a. This bottom panel plots the fraction of public feedback scores assigned in a given month into four bins, [1, 3), [3, 4), [4, 4.99), and 5 stars, over time.
2.4 Evidence from other online marketplaces

Before exploring the causes for the pattern observed in Figure 1b, we turn to the question of whether the observed increase in feedback scores is specific to the focal platform or a general feature of reputation systems. Although there is substantial evidence of right-skewed distributions of ratings at a moment in time (Nosko and Tadelis, 2015; Athey et al., 2019), we are unaware of other research showing that this right-skewness arises over time rather than being present at launch. For this reason, we obtained data from four other online marketplaces, two of which contain city-level data.

The average feedback scores for the various marketplaces are shown in Figure 2. Panel (a) shows longitudinal data in a competing online labor market. Panel (b) plots longitudinal ratings data from four major cities in the United States and Europe in a large home-sharing platform. Home-sharing platforms are peer-to-peer marketplaces that facilitate short-term rentals for lodging (Filippas and Horton, 2018). Panel (c) plots numerical feedback data from an online marketplace that facilitates the short-term rental of a durable asset (Sundararajan, 2013; Filippas et al., forthcoming). Panel (d) plots longitudinal ratings data from six major cities in the United States in a large online marketplace for services.

The goods and services that are transacted in these marketplaces differ. In panel (a) ratings are assigned by employers to workers, in panel (b) by guests (those who are renting properties) to hosts (those who are renting out properties), in panel (c) by users (renters of the asset) to users (providers of the asset) after the transaction has taken place, and in panel (d) by consumers of the service to providers of the service. Furthermore, these platforms greatly differ in the marketplace mechanisms they employ. For example, in the home-sharing marketplace renters choose the provider, but in the service marketplace the platform assigns a nearby available provider to the consumer upon request of the service. However, the reputation system mechanisms of these marketplaces are more or less identical: transactions are personal (peer-to-peer), ratings are given after the transaction has taken place and are consequential for the rated party, and the platforms all utilize mechanisms that prevent “tit-for-tat” rating behavior.

Despite the differences in what is being transacted, we observe an increase in ratings over time that mirrors the pattern that we found in the focal marketplace. This provides us with evidence that increasing feedback scores are likely common in online marketplaces with similar reputation system characteristics, even when other marketplace characteristics vary, and irrespective of the transacted goods and services.
Figure 2: Longitudinal buyer-on-seller feedback scores for a collection of online marketplaces

Notes: This figure plots the average public feedback scores assigned in four online peer-to-peer marketplaces. Scores are assigned by employers to workers in panels (a), by guests (users renting properties) to hosts (users renting out properties) in panel (b), by renters (those renting the durable asset) to providers (those renting out the durable asset) in panel (c), and by customers to providers of a service in panel (d). In panel (d), average feedback scores are demeaned by subtracting from all observations the average feedback score on the platform during the first period of data collection. In all platforms, scores are assigned upon the completion of each transaction, and the scale for feedback is 1 to 5 stars. For each observation, average scores are computed for every time period, and a 95% interval is depicted for every point estimate.

3 Decomposing changes in reputation

The previous section documents a substantial increase in feedback scores over time across five online platforms. Two broad sets of reasons may have led to substantially higher feedback scores: (1) rater satisfaction has increased, and (2) raters have lowered their rating standards.

Rater satisfaction can change over time, even if standards remain fixed. Reasons include platform improvements such as search and recommendation features resulting in better employer-worker matches, employers and workers becoming more experienced or exerting more effort, higher-quality cohorts of employers and workers joining the platform, employers incurring lower transaction and uncertainty costs by continuously transacting with a subset of desirable workers, and lower prices. Improvements in these marketplace fundamentals would result in higher average transaction quality, and hence higher feedback scores.

We cannot hope to account for all potential changes in fundamentals—and detect the
increase in scores due to changes in standards. Instead, we can sidestep this issue by employing alternative measures of rater satisfaction. Let \( u_i \) denote the utility employer \( i \) obtains after some transaction. Employer utilities are unobservable, and potentially affected by both fundamentals-related and idiosyncratic reasons, which are also unobservable and may change over time. Upon receiving utility \( u_i \), employer \( i \) leaves primary feedback

\[
s_i = S(u_i) + \sigma_i,
\]

where \( S(\cdot) \) is common amongst employers and monotonically increasing in the latent utility, and \( \sigma_i \) captures idiosyncratic differences in employers’ rating behavior. For simplicity, we ignore discrete feedback scores, and instead assume that feedback scores are continuous scores with a noise component. Employer \( i \) also leaves an alternative feedback measure \( a_i \), that we can similarly decompose into

\[
a_i = A(u_i) + \alpha_i.
\]

Assume that, at time \( t \), utilities follow some latent distribution \( F \). Let \( U \) denote a collection of observations, such that for all \( u_i \in U \) we observe the measures of satisfaction \( s_i(u) \) and \( a_i(u) \), but we do not observe the actual utility \( u_i \). We can use \( U \) to estimate a function \( \hat{s} \) from the alternative feedback measure to the primary feedback measure, i.e.,

\[
\hat{s}(a(\cdot)) = s(\cdot) + \epsilon,
\]

where \( \epsilon \) is the estimation error. Essentially, \( \hat{s} \) estimates the conditional expectation \( \mathbb{E}[s|a] \), that maps the alternative measure \( \alpha_i \) to the primary measure \( s_i \).

Assume now that at some latter period \( t' \), employer satisfaction has shifted, i.e., the latent utility distribution has changed to \( F' \), and employers’ rating standards have also shifted, i.e., the primary feedback measure has changed to \( S' \). Although we no longer observe \( s_i \) and instead observe \( s'_i \), the function \( \hat{s} \) allows us to recover what the average value of the feedback measure \( s_i \) “would” have been had rater standards not shifted. We get

\[
\Delta_s = \int s'(u) - \hat{s}(a(u)) \, dF'(u) = \underbrace{\mathbb{E}_{F'}[s'] - \mathbb{E}_{F'}[s]}_{\text{reputation inflation}} - \mathbb{E}_{F'}[\epsilon].
\]

Insofar \( \mathbb{E}_{F'}[\epsilon] = 0 \), we can estimate the extent of reputation inflation under the utility distribution \( F' \). Crucially, if the alternative measure \( a \) is also subject to inflation or if \( \mathbb{E}_{F'}[\epsilon] > 0 \), then the estimate \( \Delta_s \) provides a lower bound for the inflation term.
Using an alternative feedback measure to estimate reputation inflation circumvents the problem of estimating latent utilities from observational data, but presents us with a different—albeit more tractable—problem of verifying that $\mathbb{E}_{\mathcal{P}'}[\epsilon] = 0$. The $\mathbb{E}_{\mathcal{P}'}[\epsilon]$ term can be non-zero due to (i) differential selection of latent utilities of which $\hat{s}$ over- or under-estimates in expectation, and (ii) because of systematic changes in how raters translate their utilities to the primary and alternative feedback measures. The former condition is directly testable, while the latter needs to be theoretically reasoned through.

In what follows, we employ “private” and written feedback as two alternative measures of employer satisfaction. We will reason why both measures are not affected by systematic biases, and hence why they are subject to less inflationary pressure.\(^7\) In addition to our alternative measures approach, we provide direct tests in Appendix A that show that the most plausible selection and composition stories cannot explain the observed increase in feedback scores.

### 3.1 Private feedback as an alternative measure

Our first alternative measure of rater satisfaction comes from a platform experiment that elicited an additional “private” feedback measure. At the completion of a contract, employers were asked to generate private feedback—in addition to public feedback. Critically, the platform let the employers know that private feedback would not be shared with other workers or employers, and would only be collected by the platform for internal evaluation purposes. As it was less costly for workers, this private feedback offers an alternative measure that is potentially less subject to inflation.\(^8\) Employers were initially asked the private feedback question, “Would you hire this freelancer[worker] again, if you had a similar project?” Appendix B.1 shows that employers were substantially more candid in their private feedback. Starting on June 2014, employers were instead asked to rate workers on a numerical scale of

\(^7\)Our decomposition task is conceptually similar to estimating monetary inflation in the presence of quality changes (Sidrauskis, 1967; Friedman, 1977; Mishkin, 2000; Berentsen et al., 2011). Although quality changes are acknowledged, they are typically sidestepped by a “basket-of-goods” approach (Diewert, 1998). The implicit assumption underlying such methods is that consumers derive the same satisfaction from some “basic” goods and services, irrespective of the time period—a consumer derives equal utility from a loaf of bread in 2000, as she will in 2020 (approximately, and, of course, not from the same loaf of bread). Issues with such measures of monetary inflation mostly arise when aggregate consumer utility from “basic” goods and services changes and is hard to measure, such as for goods including phones, computers, and even cars. In the context of online markets, however, there is no “basic” or “standard” transaction, i.e., a transaction with an immutable associated rater satisfaction. Another approach—which we do not take in this paper—attempts to debias consumer satisfaction estimates directly (Huang and Sudhir, 2019).

\(^8\)Even if employers believed that the platform would use the private feedback information—for example, to suggest areas of improvement to workers—private feedback was not publicly displayed, and hence was less consequential for worker’s future outcomes than public feedback. As such, private feedback was subject to less inflationary pressure than public feedback was—we elaborate on this argument in Section 4.
0 to 10, answering the question “How likely are you to recommend this freelancer to a friend or colleague?”

Figure 3a reports the average monthly feedback over time, for the numerical public and private feedback during the period that both were collected. To make the two scores comparable, we normalize them by the first observed mean. In the language of Section 3, we use \( \hat{s}(a_t) = (a_t - a_0)/a_0 \), which has the advantage of simplicity. Public feedback scores exhibit a small increase during the period of interest (as we saw in Figure 1b). However, for the same period of time, private feedback scores exhibit a strong decreasing trend.

It is critical to stress that the average feedback scores shown in Figure 3a are being assigned by the same employers on the same contracts. The decreasing private feedback scores hence suggest a decline in rater satisfaction, and yet public feedback increased. As such, it is hard to rationalize some change in fundamentals alone that could generate this pattern. What seems more probable is that public feedback scores are subject to inflation, whereas the private scores are not because of their private nature.\(^9\)

### 3.2 Written feedback as an alternative measure

Our second alternative measure of rater satisfaction comes from written feedback. In contrast to private feedback, we have written feedback over the entire platform history. Similar to the private feedback, there are several reasons that the costs to the rater for giving “negative” written feedback are lower than for numerical feedback. First, it is harder for workers to complain about textual “tone” than it is to complain about a non-perfect star rating. Furthermore, the platform does not aggregate written feedback or put it on a scale, and does not present the written feedback to the employer during the initial worker screening phase—only average numerical feedback scores are presented, and written feedback is harder to access. As such, written feedback cannot be used for cross-worker comparisons by future employers as easily as numerical feedback does; these comparisons are precisely what makes feedback consequential for workers.

To make the two kinds of feedback comparable, we fit a predictive model, \( \hat{s}(\cdot) \) that predicts numerical feedback scores from the feedback text. The predictive model is fit on a narrow time window, using the written feedback corpus as the training set and the associated numerical scores as the set of labels. Each written feedback left by an employer post-transaction is one instance in our data. To learn the predictive model, we use a standard natural language processing pipeline. For the preprocessing step, the text of each employer-on-worker review is stripped of accents and special characters, is lowercased, and stopwords

\(^9\)Appendix B presents a series of robustness checks, ruling out other assumptions that could rationalize the divergent trends—e.g., that private standards are getting harsher although transaction quality is increasing.
Figure 3: Using alternative measures of rater satisfaction to quantify reputation inflation

(a) Numerical public feedback score and private feedback score.

(b) Numerical public feedback score and predicted score from textual feedback

Notes: This figure presents evidence of reputation inflation in public feedback scores by employing alternative measures of rater satisfaction. The top panel shows the evolution of the average public feedback scores (solid line) versus the average private feedback scores (dashed line) assigned by employers to workers, for the same contracts. The average scores are computed for every month, and are normalized by the value of their respective first observation (June 2014). A 95% confidence interval is shown for each mean. The bottom panel shows the evolution of average public feedback scores (solid line) versus the average predicted score of textual feedback (dashed line) assigned by employers to workers. A 95% interval is depicted for every point estimate. The shaded area indicates the quarters from which training data was obtained for the corresponding predictive model. The training sets consist of 1,492 reviews.
are removed. A matrix of token counts (up to 3-grams) is created, and is weighed using the TFIDF method. To find the best-performing algorithm, we conduct an extensive grid search, evaluating each configuration of hyper-parameters using a 5-fold cross validation in terms of average squared error. We then use the fitted model to estimate out-of-sample feedback scores of the written feedback for the entire sample.

The average quarterly feedback scores over time, for both the numerical public feedback, and the feedback predicted from the written feedback, are plotted in Figure 3b. As expected, the two scores match up during the training period. Going forward, both scores increase, but the predicted feedback score increases at a much slower rate. On average, numerical feedback goes from 3.96 in the beginning of 2006 to 4.86 stars at the beginning of 2016. In contrast, the average score predicted from the written feedback only goes to 4.25 stars.

The divergence between written sentiment and numerical feedback implies that a substantial amount of the increase in numerical feedback scores is due to lower rater standards. Our approach also allows us to quantify the degree of inflation: the point estimate is that 67.7% of the increase in feedback scores is due to inflation.

Importantly, written feedback can certainly become “inflated,” with work that would have elicited a “good” now garnering a “great.”¹⁰ We have some evidence that written feedback does inflate, in that the private feedback scores were declining while the sentiment of written feedback was increasing (see Figure 3). Regardless, to the extent that written feedback is also subject to inflation, our approach will underestimate the magnitude of the inflation in scores, and hence our estimates can be interpreted as lower bounds.

Our approach requires the assumption that there is no selection with respect to bias in the model or the rater. Although this assumption is not directly testable, in Appendix C we report a number of tests looking for evidence of selection bias with respect to the written measure, finding no evidence against our assumption. Furthermore, in Appendix C we also verify that employing different training periods and/or predictive algorithms yield similar results.

A potential threat to our approach is that the lexical composition of reviews could presumably changes over time; in the language of our model, $a(u_i)$ has shifted to $a(u_i) + h(u_i)$. While we have no evidence that supports this hypothesis, in what follows we take an alternative approach: as a more direct measure of inflation from written feedback, we can examine whether the same sentences found in written feedback correspond to different feedback scores at different points in time. The advantage of this approach is that it does not depend on the choice of predictive model.

¹⁰One written feedback in our data reads: “This is the most impressive piece of coding in the history of software development!”
We select written feedback from 2008 and 2015, and find all lexically identical sentences generated in these periods. We then compare average feedback by sentence, across the two periods. To illustrate this approach, Figure 4 shows the average numerical feedback scores for a set of commonly used short sentences, by period. We select sentences spanning both “good” and “bad” feedback, and which most frequently occurred in the corresponding written feedback in our data. Across terms, we see that the numerical feedback scores associated with identical sentences have increased considerably over time, and that this increase has affected both positive and negative sentences.

Figure 4: Difference over time in the feedback scores associated with identical sentences.

![Chart showing feedback scores over time](chart)

**Notes:** This figure shows the average numerical feedback associated with identical sentences found in the text of employer-on-worker written feedback, in 2008 and 2015. The sentences plotted are the four most common sentences associated with high feedback scores, and the four most common sentences associated with low feedback scores. A 95% confidence interval is shown for each mean.
4 Conceptual framework

We next provide a conceptual framework to help explain the implications of our empirical findings, and to examine why reputation inflation occurs. Toward that end, we develop a model of reputation inflation in the reputation system of a competitive labor market. Our motivating example is a labor market, but the same framework can be applied to the more general case of buyers and sellers giving feedback.

The focus of the model is the employers’ decision to either candidly assign “bad” feedback following a bad experience, or to lie and assign “good” feedback. This assumption is motivated by the strategic misreporting we observed in our data—reviewer choose to leave “good” public feedback despite an unsatisfactory experience, at least as stated in private.\textsuperscript{11}

In our model, employers have an incentive to truthfully assign “bad” feedback after a bad experience, captured by a positive benefit associated with truth-telling. This benefit includes idiosyncratic reasons to report truthfully as well as platform-specific benefits, such as awards by other users for being an accurate reviewer.\textsuperscript{12} At the same time, employers also incur a cost when they assign “bad” feedback, which is increasing in the cost of the workers from receiving this “bad” feedback. This “reflected” disutility includes the employer’s aversion to harming the worker’s future prospects, the cost of the worker complaining or withholding future cooperation, and even the cost from other workers being unwilling to work for the employer in the future if the employer has a reputation as a “strict” rater.

4.1 Setup

Consider an online labor market composed of workers and employers. Workers are matched at random with employers, after which workers produce output $y \in \{0,1\}$. The worker produces output $y = 1$ with probability $\Pr(y = 1|q) = q$, from which the employer obtains utility equal to 1, by selling the output on some product market. The employer obtains zero utility in the case that output $y = 0$ is produced.

Workers are characterized by their quality $q \in \{q_L, q_H\}$, with $q_L < q_H$. Employers know the fraction of high quality workers in the marketplace, which we denote by $\theta$. After the employer observes the worker’s realized output $y$, she generates a signal to the marketplace in the form of feedback $s \in \{0,1\}$, where $s = 1$ denotes “good” feedback, and $s = 0$ “bad”

\textsuperscript{11}Note that employers never strategically misreport a good private experience in our data, that is, employers never report “good” private feedback but “bad” public feedback. As such, employers’ choice in our model is restricted to whether a bad private experience should be publicly reported. See http://xkcd.com/958 for a comic strip on both types of misreporting.

\textsuperscript{12}Abeler et al. (2019) find strong evidence about individuals’ preferences for truth-telling, both in 90 previous studies and in their experiments. Surprisingly, the propensity for truth-telling persists even in one-shot games.
feedback. In the next “round,” employers observe the most recent feedback assigned to the worker, and form Bayesian beliefs about the worker’s quality. We assume that both sides are price-takers, and hence workers are paid their expected marginal product, which is

\[ w_s = \Pr(q = q_H|s)q_H + (1 - \Pr(q = q_H|s))q_L. \]

The worker’s cost of bad feedback, realized in the next round, is the difference in compensation between receiving good feedback, \( w_{s=1} \), and bad feedback, \( w_{s=0} \), that is

\[ \Delta w = w_{s=1} - w_{s=0}. \]

Whenever the employer tells the truth, that is when \( s = y \), she obtains a benefit \( b > 0 \). If the worker’s output is good \( (y = 1) \), then the employer has no incentive to lie and always assigns good feedback \( (s = 1) \) to the worker. However, in the case that the worker produces bad output \( (y = 0) \) and the employer truthfully reports \( s = 0 \), the worker incurs a cost \( \Delta w \), which is the wage penalty in the next round. We assume that some fraction of this cost is “reflected” back on the employer. Employers differ in how much of this cost is reflected: let \( c_i \) be the employer-specific fraction of this cost that is reflected back on the rating employer. The employer thus incurs a cost of \( c_i \Delta w \), where \( c_i \) is drawn from some distribution \( F : [c, \bar{c}] \to [0, 1] \), with \( c \geq 0 \).

In light of these reflected costs, some employers might give positive feedback even if the worker’s output was bad, thereby avoiding the cost of giving bad feedback. This decision will depend on \( c_i \), and so employer \( i \) will not report truthful feedback if

\[ b \leq c_i \Delta w. \] (1)

Let \( p \) denote the fraction of employers that generate truthful feedback in the most recent round, and assume that \( p \) is common knowledge. When considering a particular worker that received bad feedback in the previous round, i.e., \( s = 0 \), the Bayesian employer infers that

\[ \Pr(q = q_H|s = 0; p) = \frac{\Pr(s = 0|q = q_H; p)\Pr(q = q_H)}{\Pr(s = 0; p)} = \frac{(1 - q_H)\theta}{(1 - q_H)\theta + (1 - q_L)(1 - \theta)}. \]

Note that the \( p \) term divides out as \( s = 0 \) always implies truthful reporting. In contrast, if
the worker received good feedback, i.e., $s = 1$, the Bayesian employer infers that

$$
\Pr(q = q_H|s = 1; p) = \frac{\Pr(s = 1|q = q_H; p)\Pr(q = q_H)}{\Pr(s = 1; p)} = \frac{(q_H + (1 - q_H)(1 - p))\theta}{(q_H + (1 - q_H)(1 - p))\theta + (q_L + (1 - q_L)(1 - p))(1 - \theta)}.
$$

The cost of bad feedback to a worker is then

$$
\Delta w(p) = w_{s=1;p} - w_{s=0;p} = \frac{\theta(1 - \theta)(q_H - q_L)^2}{k - pk^2},
$$

where $k = \theta(1 - q_H) + (1 - \theta)(1 - q_L)$, which is the probability that a randomly chosen worker will produce bad output.

We see from Equation 2 that $\Delta w(p) > 0$ for all $p$, implying that as long as $c_i > 0$, there is always a cost to the employer of giving bad feedback, which they must compare to their benefit $b$ from telling the truth. Further, when $p$ is large, i.e., when most of the employers truthfully report, feedback is a more accurate measure of quality, and hence the value of positive feedback increases, along with the wage penalty $\Delta w(p)$. In contrast, when the majority of firms lie, the signal from good feedback is less informative, and the wage penalty narrows, as many workers receiving good feedback actually did not produce the output. We note that this relationship between the wage penalty $p$ makes which feedback is good and bad endogenous in our model—the characterization depends on $p$, which in turn depends on the choices of all other employers, who are reacting to that wage penalty.

We now consider what an equilibrium of this market would be. Let $p_E$ denote the fraction of firms that truthfully assign negative feedback when the market equilibrium has been attained. The equilibrium fraction is found by solving the equation

$$
p_E = F\left(\frac{b}{\Delta w(p_E)}\right),
$$

to which a solution always exists for any continuous distribution function, and is unique for distributions with increasing hazard rate. The two extreme cases where

$$
p_E = \begin{cases} 
1, & \text{if } b \geq \bar{c}\Delta w(1) \\
0, & \text{if } b \leq \underline{c}\Delta w(0) 
\end{cases}
$$

correspond to an all-truthful and an all-lying equilibrium. If the benefit to assigning truthful feedback is higher than the cost for every employer, then no employer has incentive to lie
($p_E = 1$), while if the costs are too high, all employers lie ($p_E = 0$).\footnote{In the case where all employers have the same cost, $p_E$ can be interpreted as the probability of truthfully generating public negative feedback in the resulting mixed strategy equilibrium.} To the extent that we think of employers as both strategic and narrowly self-interested, the all-lying equilibrium is the likely equilibrium, as the benefit $b$ is likely small or sometimes even zero, while the employer-specific costs $c_i$ could be substantial.

4.2 Discussion

Our model gives reflected costs a large role. These reflected costs can explain the divergent trends between public and private feedback observed in Section 3.1: private feedback scores are not observable by other employers when they are making hiring decisions, and hence receiving “bad” private feedback is less costly for workers. As a result, employers are more truthful in private, and less truthful in public. We test the reflected cost assumption and further examine its underlying mechanisms in Section 5.

Our model can also help provide explanations for additional aspects of the reputation inflation. In Appendix D.1, we examine the equilibrium convergence process under a simple matching scheme, where employers and workers match and transact randomly in every round. We find that reputation initially inflates fast, but then flattens out as the equilibrium fraction is approached. This finding mirrors the pattern we observed empirically in all marketplaces we have data spanning their entire operations.

One prediction of our model is that reputation inflation will be acute when workers’ costs from receiving “bad” feedback are high, and hence employers’ reflected costs are high as well, thereby inducing employers to be less truthful in equilibrium. We provide a numerical simulation illustrating this point in Appendix D.2.

5 Effects of making feedback consequential

The framework of Section 4 proposes a process by which reputation inflates. A key feature of the framework is that an employer misreports following a bad experience if $b \leq c_i \Delta w$ (see Equation 1). If the cost of “bad” feedback to the workers is zero, then employers should be truthful for any positive value of $b$, and thus would generate more “bad” feedback. If the cost of “bad” feedback to the workers changes, then the fraction of truthful employers should also change. Furthermore, as the cost of “bad” feedback is endogenous, our model also predicts a convergence to new equilibrium following a change in costs. As such, in the event that the costs of assigning “bad” feedback change, we do not expect to see a “jump”
to the new equilibrium, but rather a gradual convergence to some new equilibrium.

Recall from Section 3.1 that employers were more candidate about bad performance in private than they were in public. Our interpretation of public versus private feedback is that for “bad” public feedback, the cost to the worker, $\Delta w$, was higher than for the cost of “bad” private feedback. As a result, private feedback was more candid, i.e., more employers were more likely to report $s = 0$ when $y = 0$, as the employers’ costs were increasing in the workers’ cost of negative feedback.

We now consider what happened when the platform made a change that raised the cost $\Delta w$ of assigning “bad” private feedback. The change was the platform’s announcement in March 2015 that the private feedback ratings would be used to compute a new aggregate feedback score for workers. The aggregate score on a worker’s profile was only updated after the worker received five new feedback scores, to prevent workers from identifying which employer gave them which feedback. This score would be shown on the profile of each worker and therefore be publicly available, but anonymous in the sense that workers could not associate individual scores with employers.

To the extent that employers used this new score in their hiring decisions, the workers’ cost of “bad” private feedback increased. In the logic of our model, the platform’s hope was that by not allowing workers to know which employer gave feedback, the distribution of $c$ would remain unaffected and close to zero, even though $\Delta w$ increased. However, if many employers simply do not want to hurt the worker or fear some other kind of generalized ex post retaliation, then even the batched release of private feedback scores would keep the weight of the distribution of $c$ above 0, which should cause the private feedback measure to inflate from the all-truthful equilibrium to some new equilibrium.

Of course, simply observing that the time series of numerical private feedback rises after the platform change does not prove inflation. The new feedback system was intended to improve matches, and so the same concern from our earlier analysis applies—namely that any increase in the private feedback score following revelation reflects changes in fundamentals. For example, if employers could now form better matches because of their access to the private feedback score measure, then we would expect higher future private feedback scores. As before, we address that concern by using written comments to construct an alternative measure of employer utility.

Figure 5 plots the monthly average private feedback and the monthly average predicted private feedback, using the same modeling method we used earlier in Section 3.2. In each panel, the monthly averages are shown by type, as well as the fitted values under different regression specifications. The predicted private feedback is the prediction of a model trained during a period before the revelation, which is indicated with a shaded region. The day the
platform switched to batched public revelation is indicated with vertical dashed line. The figure shows that prior to public revelation, the actual and predicted private feedback are quite similar, but that after public revelation, the actual numerical rating increases while the predicted rating does not.

To quantify the effect of revelation, we switch to a regression framework. However, as we have some choice over the regression specification, the different panels of Figure 5 show various alternatives. In the top panel, we report the simplest specification, which is for the treatment to simply have a level effect and to allow the two feedback-types to differ by a fixed amount before the change. We can see that this specification clearly fails to capture the underlying time trend in both series, and especially for the numerical feedback in the post period. In the next panel down, the specification maintains the assumption of a level feedback, but includes a week-specific effect. This specification better captures the underlying trend in both measures that caused the previous specification to perform poorly, but it still performs inconsistently in the post-period, over-estimating the actual feedback early in the period, and then under-estimating it later, and vice versa for the predicted feedback. This is consistent with the simple level-change specification not capturing some of the dynamics of the effects of the treatment e.g., a change in slopes.

In the third panel from the top, we give both types of feedback a common linear time trend, but then allow that trend to change in the post-period for the actual feedback. With a common slope, the fit in the pre-period is much better than when we forced the two types to only differ by a level (in the top panel). However, we can see that earlier in the pre-period, only allowing a linear change in slopes under-predicts the actual feedback score, suggesting some immediate effect and not just a change in slopes.

In the bottom panel, the specification allows for both a level treatment effect and a change in slopes. This specification seems to work the best, with the predicted series closely matching the realized value. We will make use of this insight when we switch to estimating the effects of public revelation at the level of the individual contract rather than at the level of monthly averages. This has the advantage of allowing us to directly control for employer-specific effects and thus directly control for some of the potential sources of bias.

As our interest is in the divergence between the public and private feedback scores, we switch our outcome to \( \Delta s_i \), which is the numerical private feedback rating minus the predicted private rating based on the sentiment of the written text. By taking this difference, we eliminate the need (or the possibility) of including time-based fixed effects.

Table 1, Column (1) reports an estimate of the effects of public revelation on the gap between the actual and predicted feedback scores. We can see that after the switch to revelation, the gap increased. The effect size of 0.13 is about 8% of the population standard

Notes: This table reports regressions where the outcome is the monthly aggregate feedback and the predictor is an indicator variable for the private feedback revelation. Both specifications control for month-specific effects, with Column (1) utilizing a fixed effects model, and Column (2) a random effects model. Significance indicators: $p \leq 0.05 : *$, $p \leq 0.01 : **$, and $p \leq .001 : ***$.

One limitation of including all assignments as the unit of analysis is that it over-weights employers and workers with many contracts. In Column (2), we restrict the sample to employers and workers with fewer than 25 completed contracts in total. We can see that the effect size is somewhat larger with this restricted sample, but is broadly similar in magnitude.

As we noted in Section 3, one reason why a gap might emerge between some measure and an alternative measure is that in the post-period is selection of raters with idiosyncratically large or small gaps. To assess this possibility, in Column (3) we add an employer-specific fixed effect to the regression. The effect size is somewhat smaller when the fixed effects are included, but the coefficient implies that the increase in the gap between the private numerical rating within employers is quite close to the average effect.

As we saw in Figure 5, there was visual evidence for a change in the trend and not just a level difference. As such, for our preferred specification, in Column (4), we include both a post-indicator and a linear time trend for the post period and continue using the restricted sample and the employer-specific fixed effect. We can see that some of the treatment effect detected in Columns (1)-(3) was the accumulation of a trend of an increasing gap in the post-period.
6 Conclusion

This paper documents that the reputation system in an online marketplace was subject to inflation—we observe systematically higher scores over time, which cannot be fully explained by improvements in fundamentals. Data from four other marketplaces exhibit the same trend, suggesting that reputation inflation is widespread. We develop an approach to quantify inflation based on using alternative measures of rater satisfaction. A market intervention that increased the the costs of negative feedback by making previously private feedback public, yielded data supporting the role of “reflected” costs as the root cause of inflation.

Reputation inflation is likely most acute in peer-to-peer platforms, such as online labor and sharing economy markets, where wage penalties for workers and employers’ “reflected” costs are high. Reasons for the higher worker cost of negative feedback include that feedback scores are often the sole signal of quality, workers are typically highly substitutable and have few transactions, and hence each rating is more consequential. As transactions are more personal, the “reflected” costs for employers are also likely higher. In contrast, when individuals assign feedback to products (e.g. movie reviews) there is likely no reflected cost, and inflation will be less acute. Indeed, numerical scores on such platforms are characterized by lower averages, a higher spread, and, in some cases, a decreasing temporal pattern (Cabral and Hortaçsu, 2010; Moe and Schweidel, 2012; Godes and Silva, 2012).

Reputation inflation is seemingly also present in the non-digital world. For example, there is widespread concern about grade inflation, and some schools have taken steps to counter it (Butcher et al., 2014). The debate found in this literature mirrors many of the issues we examine in this paper, namely whether the increase in grades is due to fundamentals, such as better student cohorts, or due to lower rating standards, and whether information is lost. The grade inflation literature also considers some negative effects of this inflation, such as that inflated grades seemingly reduce student effort (Babcock, 2010). Exploring the consequences of reputation inflation would be an interesting next step. We present some evidence that feedback scores have become less informative over time in our focal marketplace in Appendix E.

For would-be marketplace designers, our paper illustrates a core market design problem, and elucidates its root cause. Whether there are effective platform design responses to this phenomenon is an open question. Platforms could provide monetary incentives for users who generate feedback, as dissatisfied users often leave no feedback (Nosko and Tadelis, 2015), but this approach could be costly to implement. Platforms could also emphasize reviewers as performing a service for fellow consumers, or provide other incentives for “honest” reviews: Yelp employs mechanisms such as badges for top reviewers, and makes the feedback
score distribution of each reviewer publicly accessible. Mandatory grading curves are often employed in non-digital reputation systems, although it is challenging to force a distribution in settings where buyers evaluate sellers as a “flow.”\footnote{14}{Officer evaluation reports in the US Army limit senior raters to indicating only 50\% or less of the officers they rate as “most qualified.”}

Platforms already take steps to lower “reflected” costs. These steps, such as simultaneously-revealed ratings (in place since the start of the platform) and anonymizing ratings through aggregation (as was the case with the private feedback change), did not prevent inflation from occurring in our data. Recent research from other domains suggests that the aggregate effect of retaliation concerns is not the primary source of “reflected” costs; Fradkin et al. (2019) find that introducing simultaneously revealed Airbnb reviews reduced the percentage of 5-star ratings by only 1.5\%. Similarly, while Proserpio and Zervas (2017) find that hotels replying to bad reviews on a travel review website decreases the number of users who leave negative feedback, Chevalier et al. (2018) provide evidence that managerial responses have the opposite effect, stimulating negative feedback.

Our analysis of the private feedback revelation quasi-experiment supports that “reflected” costs are to a large part due to raters incurring a greater personal cost—or guilt—the greater the harm they impose on the rated worker. An interesting alternative explanation would be that, once private feedback is revealed, workers are more likely to let the employers know that private feedback ratings have become consequential. In turn, employers may feel more pressure to leave higher private feedback ratings, or may become better informed about how harmful “bad” private feedback is. Furthermore, workers may offer to make up for a bad experience in return for a higher private feedback rating. An interesting next step is to disentangle the effects of these channels.

A Other reasons for the feedback score increase

Figures 1 and 2 document an over-time increase in numerical feedback scores. This increase may be the outcome of changes related to employer/worker composition, experience, and selection, as well as changes in the composition of type of work that takes place on the platform. Disentangling these reasons from reputation inflation is the main purpose of our paper; we summarize our arguments below, and offer additional tests that directly rule out some plausible hypotheses.

Section 3 addresses these concerns through the alternative measures approach. This approach sidesteps the problem of estimating latent employer utilities, and instead measures how the gap between the focal and an alternative measure of employer satisfaction changes over time. Another advantage of this approach is that, insofar the alternative measure of satisfaction is also subject to inflation, we underestimate the degree of reputation inflation, and hence we produce a conservative estimate. One potential problem with this approach is that there may be systematic changes in how raters translate their utilities to the primary and alternative measures. This hypothesis is not supported by our data, as (1) using private feedback as an alternative measure of employer satisfaction, we restrict our attention to a short time horizon where such changes are unlikely to have take place, and (2) using written feedback as an alternative measure, results, we find similar patterns and estimates of inflation regardless of the training period employed in learning the \( \hat{s} \) function. Another potential drawback of this approach is that learning the \( \hat{s} \) function may introduce an estimation error. There is no evidence that this is the case in our data, because (1) the \( \hat{s} \) function employed for translating private feedback to numerical feedback is very simple, and (2) several different \( \hat{s} \) functions for translating private feedback to numerical feedback yield qualitatively similar results; we provide further details in Appendices B and C.

While our view is that the alternative measures approach provides strong evidence supporting the reputation inflation story, we believe it is useful to also offer supplementary evidence directly ruling out plausible alternative hypothesis for the observed increase in feedback scores. Plausible alternative explanations include that better employer and worker cohorts are active on the platform, that employers continuously transact with a subset of desirable workers, and that job composition skews towards inherently higher-rated tasks.

Changes in employer and worker composition could result in different trends in the observed increase in feedback scores. In Figure 6, panels (a) and (b) we plot the average employer feedback scores for the first transactions of employers and workers respectively, whereas panels (c) and (d) depict the average feedback scores only for transactions in which employers and workers respectively are experienced—employers and workers with more than
Figure 6: Monthly average feedback scores assigned by employers to workers for various subsets of the online labor market data.

Notes: This figure plots the average public feedback scores assigned in the focal online labor market. Scores are assigned by employers to workers upon the completion of each transaction, and the scale for feedback is 1 to 5 stars. For each observation, average scores are computed for every time period, and a 95% interval is depicted for every point estimate. Panels (a) and (b) plot average scores for the first employers’ and workers’ transactions respectively. Panels (c) and (d) plot transactions where employers and workers respectively, had more than 4 previous transactions on the platform. Panels (e) and (f) plot average scores for each employer-worker pair’s first, and followup transactions respectively. Panels (g) and (h) plot average scores for transactions with cost of less than 100 and more than 1000 U.S. dollars respectively, and panels (i) and (j) plot average scores for the two most common freelancing tasks. We obtain quantitatively similar results when we choose other thresholds to define “experience,” when we choose other thresholds to define “cheap” and “expensive” transactions, and when we restrict our sample to various other freelancing tasks.

Four previous transactions in the platform. Strikingly, the same trend persists across all subpopulations, suggesting that the observed increase is not a function of experience: inexperienced employers give higher ratings over time, and inexperienced workers also receive
higher ratings. The average scores of experienced users are only slightly higher than those of first-time users, suggesting that some selection takes place, but subpopulations exhibit the same over-time increase.

The observed increase in feedback scores could also be explained by trading partner selection, that is, employers identifying a subset of desirable workers, and continuously transacting with them. In Figure 6, panel (e) plots average feedback scores only from first-time transactions between an employer-worker pair, whereas panel (f) plots average feedback scores from follow-up transactions—transactions where the employer-worker pair has transacted in the past. When an employer chose to transact with the same worker, we expect that the employer was more satisfied. Indeed, we observe that average scores start higher, yet we see a similar over-time increase in average numerical scores across both subpopulations.

An additional piece of evidence against this type of selection comes from the observed trends in the marketplaces depicted in Figure 2. In the home-sharing marketplace, it is unlikely that selection is a major factor, because users are unlikely to travel to the same destination for leisure repeatedly. In the service marketplace, the platform matches providers with consumers, and hence selection is ruled out by default. Furthermore, provider/worker capacity is highly constrained in all marketplaces, making it unlikely that the same provider will be available in the future. Together, this empirical evidence supports that selection cannot explain the observed increase.

Changes in job type composition could also explain the observed trends—for example, the type of transactions taking place in the focal marketplace could skew towards an inherently highly-rated transaction type over time. In Figure 6, panel (g) plots average feedback scores for transactions worth less than 100 US dollars, panel (h) plots average scores for transactions worth more than 1000 dollars, and panels (i) and (j) plot average scores for the two most frequent types of tasks. The feedback scores for these job subpopulations exhibit a strikingly similar pattern, supporting the view that the composition of types of transaction in the platform also cannot explain the observed increase. Furthermore, an additional piece of evidence comes from the fact that the types of products and services transacted in the marketplaces depicted in Figure 2 remain constant throughout our data collection period.
B Robustness tests for private feedback

B.1 Comparing private and public feedback

Employers assigned both public and private feedback for the same contract. Figure 7 shows the distribution of public feedback, conditioned on the private feedback. The percentage of employers giving that feedback score is shown in parenthesis in each panel. Although the most common response was “Definitely Yes,” about 15% of the employers gave unambiguously bad private feedback (“Definitely Not” and “Probably Not”). In contrast, during the same period less than 4% of the employers gave a numerical score of 3 stars or less. Given this gap, we might suspect that some employers expressing a negative private sentiment are less candid in public.

Employers who leave more negative private feedback do assign lower public feedback scores: among those employers that selected the “Definitely No” answer to the private feedback question, 29.1% assigned a 1-star rating publicly. Surprisingly, however, the second most common choice for these employers at 15.7% was in the 4.75 to 5.00 bin, and 28.4% publicly assigned more than 4 stars. In short, many privately dissatisfied employers publicly claimed to be satisfied. We can see that the reverse—privately satisfied employers giving bad public feedback—essentially never happens. Employers who selected “Definitely yes” left very positive public feedback, with more than 95% of these observations falling into the highest bin.

B.2 Misinterpreting private feedback

One concern with any new feedback feature is that raters might simply not understand the new ratings. However, we have evidence that employers, at least collectively, understood quite well what the scale meant. When asked for private feedback, the platform also displayed a set of reasons that the employer could optionally select to indicate the reason for their score. Positive reasons were shown when the assigned feedback was above 5, while negative reasons were shown otherwise (during the 0 to 10 scale period). We use this “reason” information to verify that employers did not misinterpret the private feedback question. The fractions of private feedback reports citing these different reasons against the assigned private feedback score (1 to 10 scale) are plotted in Figure 8. We can see that there is a clear trend in the “correct” direction for both scores, indicating that private feedback scores were correctly assigned, at least on average.

Notes: This figure plots the distribution of public feedback scores, computed separately for every set of users that gave the same answer to the private feedback question. The red dotted line plots the cumulative distribution function.

B.3 Selection issues

Another plausible concern is that employers could be self-selecting into when they will leave private feedback, and that changes in private feedback scores reflect changes in the selection process. Figure 9 plots the evolution of numerical public feedback for all contracts (solid line), and contracts for which private feedback was also assigned (dashed line). We observe that contracts in which private feedback is also assigned receive higher average public ratings, implying that employer who publicly indicate higher satisfaction are more likely to also assign private feedback. The two lines closely resemble each other throughout the period where we collect both types of feedback, indicating no systematic change over time.
Figure 8: Fraction of users citing a given reason when giving private feedback, by score.

![Graph showing fraction of respondents citing each reason against private feedback score.](image)

*Notes:* This figure plots the fraction of feedback reports that cited each reason as the basis of the feedback being positive or negative, against the private feedback score given. Across every case, we notice that employers that assigned more extreme feedback scores tend to cite reasons of the same sentiment more frequently.

Another concern is that employers’ decision to leave private feedback when they leave public feedback could change over time. Figure 10 plots the percentage of contracts that received private feedback amongst those contracts that received public feedback. We observe that there is no systematic change over time in employers’ decisions to assign private feedback when they assign public feedback. Furthermore, the percentage of employers that choose to leave private feedback is high, with an average of 81.4% of employers deciding to also assign private feedback.

C Robustness tests for written feedback

C.1 Selection issues

A concern about the use of written feedback as an alternative measure of rater satisfaction is that employers’ assignment behavior changes over time. In what follows we conduct robustness tests to identify potential sources of bias for our analysis.

As with private feedback, a plausible concern is that employers may be more or less satisfied when deciding to assign written feedback in addition to numerical feedback. Figure 11 plots the evolution of numerical feedback for all contracts (solid line), and all contracts for which written feedback was also assigned (dashed line). We observe that contracts in which written feedback is also assigned receive higher ratings, implying that more satisfied employers assign written feedback. However, the degree to which this bias occurs does not change throughout our data. Furthermore, since written feedback is positively biased, comparing the predicted scores from text versus the evolution of all scores gives us a lower bound for the degree of inflation.

Figure 11: Monthly average numerical scores, and monthly average numerical scores when written feedback was assigned.

Notes: This figure plots the monthly average feedback scores for all contracts (solid line), and the monthly average feedback scores for contracts to which written feedback was also assigned (dashed line). Scores are assigned upon the completion of each transaction, and the scale for feedback is 1 to 5 stars. For each observation, average scores are computed for every time period, and a 95\% interval is depicted for every point estimate.

Similarly to private feedback, a concern is that employers decision to leave written feedback when they leave public feedback could change over time. Figure 12 plots the percentage
of contracts that received written feedback for those contracts that also received public feedback. We observe that there is no systematic change over time in employers’ decisions to assign private feedback when they assign public feedback. The percentage of employers that chooses to leave written feedback is also high, with an average of 79.2% of employers deciding to also assign written feedback.

Figure 12: Percentage of employers leaving written feedback in addition to public numerical feedback.

Notes: This figure plots the monthly percentage of contracts for which employers assigned written feedback, amongst those contracts for which employers also assigned numerical feedback.

C.2 Composition of raters

Shifts in the composition of raters could potentially introduce bias in using written feedback as an alternative measure of satisfaction. More specifically, the widening gap between numerical scores and scores predicted from written feedback could be the outcome of employers with this rating behavior—employers who assign higher scores for the same written feedback—joining the platform over time, or, equivalently, employers with the opposite rating behavior dropping out. In the language introduced in Section 4, this issue can be thought of as a systematic changes in $\mathbb{E}_{E'}[e]$.

We test against this hypothesis as follows. For a period of time $T$, we compute the average residual error $r_i$ for each employer $i$ that left feedback during $T$, defined as the divergence between the numerical scores and the predicted scores from the associated written feedback employer $i$ assigned. The employer average residual error is then $\bar{r}_T = \sum \text{left feedback in } T r_i$. We then test whether, amongst these employers, there is a systematic drop-out behavior
that has led to employers with wider gaps remaining in the platform in the post period (and, respectively, whether only employers with narrower gaps were present in the pre-period). We can do so by simply computing $\tau_t = \sum_i \text{feedback}_i \text{ in } T \text{ and } t \tau_i$, for any $t \neq T$. If for $t > T$ the quantities $\tau_i$ show a systematic increase, then this composition shift in rater types may bias our estimates.

Figure 13 carries out this analysis for employers who left feedback in January and February of 2009. For the predicted scores, we employ the predictions of the model in the lower panel of Figure 14. We find no evidence of a systematic trend in neither the pre-period, nor the post-period, suggesting that our inflation estimates are not subject to this source of bias. Conducting the analysis for other periods in our data or for other predictive models, yields qualitatively identical results.

Figure 13: Employer average residual error in for employers who left feedback during January and February 2009.

Notes: This figure plots the employer average residual error over time for the set of employers who left feedback during the period indicated by the shaded area. The average residual errors are computed for every month, and a 95% interval is depicted for every point estimate.

C.3 Alternative training periods

In the bottom panel of Figure 14 we perform the same empirical exercise as in Section 3.2, again plotting the average quarterly feedback over time, for both the numerical public feedback and the feedback predicted from the written feedback. However, our training sample now comes from a longer time period indicated by the two vertical red lines, and is larger,
consisting of 10,555 feedback samples. As expected, the predicted and actual scores closely match up during the training period. However, in the period before, the predicted score is higher than the numerical score, and the opposite holds after the training period. We adjust the second score by a constant, so that the predicted score matches the actual feedback score in the beginning of our data. With this adjustment, the average predicted feedback score at the end of the data “should” have only been 4.35 stars. Using the first quarter sample, the point estimate is that 67.7% of the increase in feedback scores is due to inflation, whereas the larger sample from the middle of the data implies 56.6% of the increase is due to inflation. Reassuringly, the two corpora give similar results.

C.4 Predictive algorithm performance

We present more details about the performance of the algorithms used to extract the written feedback sentiment in Section 3.2.

Figure 15a plots the scatterplot of numerical scores versus predicted scores from written feedback for the algorithm trained on data coming from the earliest quarter. Figure 15b plots the same scatterplot for the algorithm trained on data coming from the later quarters. Since the training data is skewed towards higher scores in both cases, the algorithms are expected to over-predict, but both predictive models attain good performance, with the mass of their predictions being close to the 45 degree line. Furthermore, note that this performance is attained despite the fact that we should expect somewhat large variance between scores and written feedback amongst different employers. The appropriateness and good performance of our models is further verified by the fact that the estimates we obtain closely match the performance of our model-free approach presented in Figure 4.
Figure 14: Numerical public feedback and predicted score from textual feedback using the first quarter as the training period.

Notes: This figure plots the evolution of average public feedback scores (solid line) versus the average predicted score of textual feedback (dashed line) assigned by employers to workers. A 95% interval is depicted for every point estimate. The shaded area indicates the quarters from which training data was obtained for the corresponding predictive model. The training sets consist of 1,492 samples (top panel) and 10,555 samples (bottom panel). Adjusted predicted scores (dotted line in the bottom panel) are calculated by subtracting the constant from the predicted scores that allows the left endpoints of the adjusted and actual score lines to coincide.
Figure 15: Numerical score versus predicted score from text scatterplot.

(a) Performance on training set from earliest quarter.

(b) Performance on training set from later quarter

Notes: The top panel plots the scatterplot of numerical scores assigned to contracts versus numerical scores predicted from the associated written feedback for the algorithm trained on data from the earliest quarter, while the bottom panel plots the same scatterplot for the algorithm trained on data from the later quarter. The scale for feedback is 1 to 5 stars. The 45 degree line represent the performance of a “perfect” prediction algorithm.
D Additional theoretical results

D.1 Convergence and the evolution of average feedback

We examine the equilibrium convergence process for the model developed in Section 4. Assume that in every period, employers randomly match with workers, workers produce outputs, and employers subsequently report feedback. Let \( p_t \) denote the truth-telling fraction of the employer population after period \( t \). To avoid cases where the convergence process is trivial, we will assume that the \( p_E < 1 \), that is, that the equilibrium truth-telling fraction is not the all-truthful equilibrium (see Equation 3).

Consider the case of a marketplace where every employer starts off reporting feedback truthfully, that is, \( p_0 = 1 \). After every period, a fraction \( \theta_B = (1-\theta)(1-q_L)+\theta(1-q_H) \) of the employers receives a bad output, i.e., \( y = 0 \). The employers who received a bad output then compare their benefit from truth-telling \( b \) with the cost of truthfully reporting bad feedback. Employers whose cost from truth-telling is lower than the benefit give bad feedback to the workers. As such, a fraction \( l_0 = \theta_B[1 - F(\frac{b}{\Delta w(p_0)})] \) begins to lie after the first period, and hence \( p_1 = p_0 - l_0 \).

Let \( T(x) = F(b/x) \) be the proportion of sellers that are better off truthfully reporting if the cost of bad feedback is \( x \). From Equation 3 we obtain \( T(p_E) = p_E \). Since \( F \) is a cumulative distribution function, and \( \Delta w \) is decreasing in its argument, \( T \) is a decreasing but non-negative function. As a result, \( p_2 < p_1 \), but \( l_1 < l_0 \), and hence \( p_1 - p_2 < p_0 - p_1 \). Following the same argument, we can inductively show that the dynamics of the marketplace result in convergence to the equilibrium truth-telling fraction \( p_E \), and that the rate of convergence decreases as the market approaches the equilibrium point. This is the pattern we observed empirically in all marketplaces: reputation initially inflates fast, but then flattens out as the equilibrium fraction is approached.

D.2 When is reputation inflation acute?

The conceptual framework developed in Section 4 focuses on the role of reflected costs as the main driver of reputation inflation—which we then confirm empirically in Section 5. More specifically, our model predicts that reputation inflation will be sever in contexts such as in peer-to-peer platforms, such as online labor and sharing economy markets, where wage penalties for workers and employers’ “reflected” costs are high. Some reasons for the higher worker cost of negative feedback include that feedback scores are often the sole signal of quality, workers are typically highly substitutable and have few transactions, and hence each rating is more consequential. As transactions are more personal, the “reflected”
costs for employers are also likely higher. In contrast, when individuals assign feedback to products (e.g. movie reviews) there is likely no reflected cost, and inflation will be less acute. Furthermore, institutional ratings—such as BBB and health inspection scores—are also less likely to suffer from inflation.

To provide a graphical depiction of this intuition, we plot in Figure 16 the equilibrium truth-telling percentage for different truth-telling cost to truth-telling benefit ratios. To increase truth-telling costs, we increase the mean of the distribution of “reflected” cost coefficients, keeping everything else constant. When the cost-to-benefit ratio is low, we see that most of the employers truthfully report their feedback in equilibrium. This is the case for platforms such as Yelp or movie rating websites, where the raters are giving feedback to businesses, and transactions are less personal. Furthermore, reviewers in these platforms likely view themselves as performing a service for fellow consumers, and being known for good, honest reviews is at least part of the incentive people have for participating. In the language of our model, these sites have a higher \( b \). As the cost-to-benefit ratio increases, the equilibrium truth-telling percentage approaches zero, and the average feedback scores are hence inflated: this is the case for platforms such as Uber or eBay, where the “reflected” costs are high.

Figure 16: Truth-telling equilibrium fraction as a function of the ratio of the mean cost over the benefit of generating truthful feedback.

Notes: This figure plots the equilibrium truth-telling fraction \( p_E \) as a fraction of the ratio of the average truth-telling cost \( \mu_C \) over the truth-telling benefit \( b \). The parameters used in computing the equilibrium truth-telling fractions are \( q_H = 0.8, q_L = 0.2, \theta = 0.5, b = 1, F \sim N(\mu_C, 1) \). Alternative distribution and parameter choices of parameters yield qualitatively similar results.
E Informational implications of reputation inflation

The impact of reputation inflation could be minimal if market participants “know” about the rate of inflation and adjust accordingly; even if individuals are not well-informed, the platform could implement statistical adjustments in its design of the reputation system to uncover the “true” (non-inflated) scores. However, if the pooling in the highest feedback “bin” becomes acute, statistical corrections cannot recover the lost information. This is partially due to the fact that, by design, numerical scale systems are prone to top-censoring; for the question “rate on a scale from 1 to X,” the value of X must be pre-specified.\textsuperscript{15} Changes in the reputation system, such as adding a higher ceiling in the feedback scores or additional dimensions of reputation, may temporarily mitigate—but do not solve—the problem.\textsuperscript{16}

To see the problem created by top-censoring, consider the information conveyed by the observation of a binary variable $X$, as it is captured by the information-theoretic entropy $H(X) = p \log(p) + (1 - p) \log(1 - p)$, where $p$ is the probability of one outcome. As $p$ goes to either 1 or 0, the information conveyed by the variable—in our case, the observed feedback score—goes to zero. However, this binary characterization of the reputation system is a simplification that could elide an important way in which rising—and even more compressed scores—could convey just as much (or even more) information. Consider increasing all nominal scores by some fixed amount and then “shrinking” all scores toward some new higher mean. This transformation would have no informational implications. To assess informativeness, we need to take an empirical approach.

To assess the informativeness of the feedback scores about worker quality over time, we conduct a variance decomposition, showing how the fraction of unexplained variance in feedback scores changes over time. Suppose that the data generating process of a worker’s feedback is

$$\text{SCORE}_{it} = a_{it} + c_{it} + \epsilon_{it}, \quad (A1)$$

where $a_{it}$ is the worker’s true quality, $c_{it}$ is a baseline time effect, and $\epsilon_{it}$ is some noise term such that $E[\epsilon_{it}] = 0$.\textsuperscript{17} If, over time, more of the variation in feedback scores can be explained by the variation in the noise term rather than by variation in the quality of individuals, then a feedback score is becoming less informative of the worker’s true quality.

Consider a Bayesian employer trying to infer the quality of a worker from a score: the more the feedback score is attributable to noise, the lesser its impact on the employer’s

\textsuperscript{15}This is why reputation inflation differs from monetary inflation; a sandwich that used to cost $0.50 and may now cost $12. However, this could not happen if price was mechanically restricted to be below $1.

\textsuperscript{16}See also https://www.youtube.com/watch?v=K005S4vxi0o.

\textsuperscript{17}For simplicity, we are treating the feedback score as continuous. The logic is identical in the dichotomous case.
posterior belief of worker’s quality after observing this score. To wit, let \( \Pr(a) \sim \mathcal{N}(a_0, \sigma_0^2) \) be the employer’s prior distribution for worker quality, and let \( \epsilon \sim \mathcal{N}(0, \sigma^2) \) be the noise term with known variance \( \sigma^2 \), and \( a \) be the worker’s true quality, which the employer forms a posterior about after observing a feedback score. After observing the worker’s feedback score \( \text{SCORE} \), the employer’s posterior is

\[
\Pr(a|\text{SCORE}) = \mathcal{N}\left(\frac{1}{\sigma^2}\text{SCORE} + \frac{1}{\sigma_0^2}a_0, \frac{1}{\sigma^2} + \frac{1}{\sigma_0^2}\right).
\]

From the above equation, as \( \sigma^2 \to \infty \), \( \Pr(a|\text{SCORE}) \to \Pr(a) \), or in words, as the noise component of the score explains more of the variance, the observed feedback becomes less informative, and at the limit, has no effect on the employer’s beliefs.

To explore the informativeness of feedback scores empirically, we make two assumptions. First, for a suitably small window of time (i.e., a quarter), we assume that the baseline time effect, \( c_t \), is fixed. Second, we assume that the population distribution of \( a_{it} \) can have a changing mean, reflecting shifts in worker quality, but its variance is constant; workers could be getting systematically better or worse, but their abilities are not getting more or less spread out.

The fraction of variance due to noise is the quantity

\[
\frac{\text{Var}(\epsilon)}{\text{Var}(\text{SCORE})} = 1 - \frac{\text{Var}(a)}{\text{Var}(\text{SCORE})}. \tag{A2}
\]

If this ratio increases over time, feedback scores are becoming less informative. We can easily compute this fraction for a time period \( t \) by performing the regression implied by Equation A1—the quantity of Equation A2 is \( 1 - R^2_t \), where \( R^2_t \) is the coefficient of determination from the period \( t \) regression.

We fit the regression described in Equation A1 on the feedback scores generated in every quarter of our data separately. On each of these regressions, we are using fixed worker effects to estimate \( a_{it} \), thereby allowing worker quality to evolve in time, even “within” a worker. Figure 17 plots the percentage difference of \( 1 - R^2_t \) from the minimum unexplained variance, which is found at the first period in our data. The increase in unexplained variance from 2007 to 2016 is about 118% (from 0.32 to 0.70). This strong positive trend in the explained variance implies that the relative importance of noise in explaining feedback grows over time, which in turn implies that the informativeness of feedback about worker quality has deteriorated.
Figure 17: Feedback score variance not explained by worker quality over time. Scores are reported as percentage differences with respect to the minimum unexplained variance.

Notes: Unexplained variance is reported the percentage difference with respect to the minimum unexplained variance of the time series, which is attained at the first period of this figure. The data of each quarter consists of workers with at least 2 jobs in that quarter, as otherwise the fixed effect $a_{it}$ would perfectly predict their feedback score. Utilizing different cutoffs does not quantitatively change our results.
